Implant-supported fixed full-arch rehabilitation without bone grafting in severely atrophic maxillae: A 10- to 12-year retrospective follow-up study

Abstract

Objective

The objective of this article is to assess the clinical, radiographic and patient-related outcomes of patients with severe atrophy of the maxilla (Cawood and Howell Class V) rehabilitated with fixed full-arch prostheses on dental implants placed in anatomical buttresses and remnant bone.

Materials and methods

An observational retrospective clinical study was performed with a minimum follow-up period of 10 years. An analysis of the following parameters was performed: (a) periimplant parameters (plaque index, modified gingival index, probing pocket depth and keratinized mucosa width); (b) marginal bone loss; (c) implant survival rate; and (d) patient satisfaction based on a visual analog scale (VAS).

Results

Ten patients and 71 dental implants were studied, with a mean follow-up period of 126 months (range: 120–144). The mean plaque index was 1.0 ± 0.5, with a mean probing pocket depth of 2.3 mm (range: 1.0–4.0 mm). Sixty-one percent and 39% of the implants presented a modified gingival index of 1 and 2, respectively, and the mean keratinized mucosa width was 5.8 mm (range: 4.0–10.0 mm). The mean marginal bone loss of the implants was 0.7 ± 0.4 mm (range: 0.0–5.0 mm). The implant survival rate was 97.2%, and the overall mean patient satisfaction score was 90 (range: 0–100). Prosthesis cleaning ease scored lowest on the VAS.

Conclusion

In our limited sample of patients with severe maxillary atrophy (Cawood and Howell Class V), the placement of dental implants in anatomical buttresses and remnant bone, associated with rehabilitation with fixed full-arch prostheses, was found to be an adequate treatment option in the long term regarding implant survival, marginal bone loss, periimplant clinical parameters and patient satisfaction.

Keywords

Dental implants; atrophic maxilla; fixed prosthesis; full arch; long-term; graftless.
Introduction

Tooth loss gives rise to gradual resorption of the alveolar process, with a change in bone and muscle relations and in facial morphology. While most of this resorption occurs in the first year after tooth loss, it continues throughout life and can often give rise to severe bone atrophy both vertically and horizontally. Severe bone atrophy of the maxilla (Cawood and Howell Class V) is associated with certain problems, such as reduced perioral tissue support, the impossibility of wearing complete dentures, chewing and speech alterations, and difficulties in placing dental implants owing to the limited amount of available bone.

Many surgical techniques have been proposed for the rehabilitation of this type of patient. These methods can be classified into bone grafting techniques (i.e., guided bone regeneration, onlay grafting with autogenous bone blocks, inlay autogenous bone grafting), distraction osteogenesis, crestal expansion techniques (i.e., split crest), the use of special implants (i.e., short dental implants of < 6 mm or narrow dental implants of < 3 mm) and the modification of the original implant insertion protocol to avoid bone grafting by using areas of residual bone or anatomical buttresses (i.e., zygomatic implants, pterygoid implants, implant insertion in the maxillary tuberosity, tilted implants, palatal implants and implants placed in the nasopalatine canal).

The use of bone grafting to allow implant placement in atrophic maxillae is associated with more frequent complications and higher morbidity, especially when an extraoral donor site is required. The associated increase in financial costs and a longer treatment time can lead, sometimes, to limited patient acceptance of treatment. Additionally, the use of extraoral grafts (i.e., iliac crest) has a non-predictable resorption pattern, which can be of almost the entire graft, especially in the edentulous maxilla. The use of short and narrow implants is a promising alternative concept for the treatment of the atrophic maxilla, but the lack of trials for this specific situation with follow-ups of at least 5 years indicate caution regarding results.

The use of anatomical buttresses and the residual bone is a predictable way to rehabilitate the atrophic maxilla with dental implants and fixed full-arch prostheses, and several studies detail these techniques. This approach avoids complications and morbidity associated with bone grafting, reduces treatment costs and time, and results in a high patient satisfaction overall. Nevertheless, these types of techniques are not free of complications and an expert surgeon is required, especially for zygomatic implants. Because the anatomy of the atrophic maxilla is different for each patient, it is usual in daily practice that only 1 graftless approach is insufficient, and the combined use of different techniques is essential. However, a lack of studies combining different implant approaches in the same patient exists. For this reason, we sought to study the combined use of different techniques to treat the Cawood and Howell Class V atrophic maxilla and their results in the long term.

The aim of this observational retrospective clinical study was to evaluate the implant survival rate, clinical and radiographic outcomes, and patient satisfaction in patients with severe atrophy of the maxilla rehabilitated with dental implants placed in anatomical buttresses and remnant bone and supporting a full-arch fixed prosthesis with a follow-up of at least 10 years.

Materials and methods

An observational, retrospective clinical study was performed in the Oral Surgery Unit of the University of Valencia, Valencia, Spain, from January 2017 to January 2018, involving patients with severe atrophy of the maxilla and subjected to dental implant rehabilitation. A retrospective chart review was performed to select potential candidate patients. The following inclusion criteria were established:

(a) severe atrophy of the maxilla (Cawood and Howell Class V; the minimum amount of bone for implant placement was 8 mm in height and 3 mm in width, measured at crestal level) treated with dental implants placed in buttresses and in remnant bone;
(b) rehabilitation with full-arch fixed prosthesis;
(c) good general health; and
(d) a minimum follow-up of 10 years after prosthesis delivery.

Before inclusion in the study, the patients received an explanation of the scope and purposes of the study and were asked to sign an informed consent and data confidentiality form.
Graftless implant rehabilitation of atrophic maxillae

Surgical technique

Before surgery, a panoramic radiograph and a cone beam computed tomography or computed tomography scan was taken of all patients to assess the amount of remaining bone and the presence or absence of maxillary sinus disease. Phibo TSA dental implants with the Avantblast surface (Phibo Dental Solutions) were used. The implants were placed with a combination of drills and osteotomes and were all left submerged (Fig. 1 illustrates a representative clinical case). Sutures were removed 1 week after surgery, and all patients were included in a maintenance program with control visits involving professional prophylaxis every 6 months.

Prosthetic procedure

Healing abutments were connected 3 months after implant placement, and the definitive impressions were obtained 15 days later for preparation of the definitive full-arch screw-retained fixed maxillary prosthesis. Implant loading took place 5–6 months after surgery. Fixed hybrid metal–ceramic or fixed hybrid metal–resin prostheses were used for the definitive restoration.

Study variables

Data were collected on patient age and sex, the number of implants and their dimensions, complications, and the date of prosthesis delivery. During the last follow-up visit all the prostheses were removed and the following parameters were recorded:

Clinical parameters: (a) plaque index; (b) modified gingival index according to the specifications of Mombelli;33 (c) probing pocket depth (measured at 4 points for each implant and the average calculated); (d) width of keratinized mucosa in millimeters; and (e) the implant survival rate.

Radiographic parameters: Periapical radiographs obtained at prosthesis delivery and after at least 10 years were used to calculate bone loss. Radiographs were obtained with the XMIND intraoral system (Groupe Satelec–Pierre Rolland) and an RVG intraoral digital receptor (Dürr Dental). Periapical radiographs were taken using the paralleling technique with a film holder and an aiming device (Rinn XCP, Dentsply Sirona). If the bone level around the study implants was not clearly visible, a new radiograph was taken. Periimplant marginal bone levels were measured by the same operator, using CliniView software.
Graftless implant rehabilitation of atrophic maxillae

(Version 5.1, Instrumentarium Imaging). Each image was calibrated using the known diameter of the implants. The vertical distance from the outer edge of the implant shoulder (reference point) to the most coronal bone-to-implant contact was measured to the nearest 0.1 mm. From this measurement, we subtracted the measurement of the polished neck of the implant (1.5 mm) to determine exactly the beginning of the treated part. Periimplant marginal bone resorption at the mesial and distal aspect of the implants was calculated from the change in bone level between the baseline (prosthesis delivery) and the last control radiograph available (at least 10-year control); for each pair of measurements, the largest value was used.

Patient-related outcomes: Patient satisfaction was subjectively scored with a visual analog scale (VAS; range: 1–100) used at the time of the study. This scale assessed patient satisfaction with the implant-supported prosthesis, measuring the following items: overall satisfaction, comfort and stability, ease of hygiene, ease of speech, esthetics, self-esteem, and function. The patients scored these aspects independently, though a dentist was present in case help or some explanation was needed.

Results

Ten patients with a mean age of 57 years (range: 33–72 years) were included. Of them, 5 were men and 5 women. A total of 71 dental implants were placed in the maxilla (between 6 and 8 implants per patient), with dimensions between 8.5 × 5.5 mm and 16.0 × 4.2 mm. Of these 71 implants, 32 were placed in residual alveolar bone, 3 in the nasopataline canal, 16 in the pterygomaxillary region, 12 in a palatal position, and 8 simultaneous to a sinus lift procedure, just to obtain bicortical anchorage but without the use of any type of graft (1-stage sinus lift). The mean duration of follow-up was 126 months (range: 120–144 months). At the time of the study, 7 patients had been followed up on for 10 years, 1 patient for 11 years, and 2 for 12 years. None of the patients suffered postoperative complications. Nine patients received hybrid metal–resin prostheses and 1 a hybrid metal–ceramic prosthesis. Regarding prosthesis complications, resin fracture occurred in 2 patients (1 year after loading in 1 case and 4 years after loading in the other), and the problem was solved with simple composite repair (Table 1).

Table 2 shows the main findings of the study. The mean plaque index was 1.0 ± 0.5, with a mean probing pocket depth of 2.3 mm (range: 1.0–4.0 mm). Sixty-one percent and 39% of the implants presented a modified gingival index of 1 and 2, respectively, and the mean keratinized mucosa width was 5.8 mm (range: 4.0–10.0 mm). One nasopataline implant failed before prosthetic loading, and 1 implant placed in residual alveolar bone failed after loading. The implant survival rate was 97.2%. The mean marginal bone loss was 0.7 ± 0.4 mm (range: 0.0–5.0 mm), with no differences between implant positions. The overall mean patient satisfaction score was 90 (range of the VAS: 0–100). Comfort and stability, function and self-esteem items had the mean highest values (92, 95 and 91, respectively). Prosthesis cleaning ease scored lowest (mean: 72) on the VAS.
Graftless implant rehabilitation of atrophic maxillae

Discussion

Severe maxillary atrophy poses problems for conventional implant placement. Bone grafts are an option in such cases, but are not popular among patients, owing to the long treatment times involved, the difficulties and complications related to the surgical procedure and an increase in the treatment cost.

Conventional dental implant placement in remnant bone is an effective alternative for the rehabilitation of these individuals. In this regard, the survival rate for implants in remnant bone is greater than for implants in grafted bone. Widmark et al. reported a survival rate of 87% with conventional implant placement in atrophic maxillae, versus 74% in the case of implants in grafted bone, after a follow-up period of 3–5 years. Rosén and Gynther in turn conducted a study of 19 patients with a mean duration of follow-up of 8–12 years and reported a survival rate of 97%. They concluded that implant placement in the remnant bone of atrophic maxillae is an adequate alternative to bone grafting procedures. In a study by Krekmanov et al. involving 22 patients, the survival rate was found to be 95.7% after a follow-up period of 1–5 years. More recently, Testori et al. reported a survival rate of 95.1% in a sample of 144 implants placed in atrophic maxillae with a follow-up of 10 years. In our study, the implant survival rate was 97.2% after a mean duration of follow-up of 126 months. Regarding implant position, the survival rate of the implants placed in the nasopalatine canal was especially lower. In the literature, the survival rate of this type of implant was between 84.6% and 100%. In our study, the survival rate in this regard was 66.66%. These results can be explained by the limited number of implants (n = 3).

Regarding bone loss, most authors have reported values similar to those of our own series. Aparicio et al. studied 101 conventional implants in 25 patients with atrophic maxillae and recorded a mean bone loss of 1.21 mm after 37 months of follow-up. A study by Toljanić et al. recorded a mean bone loss of 0.9 ± 0.8 mm in 46 patients after 1 year of follow-up. This figure remained stable from fitting of the prosthesis to 1 year of follow-up. Testori et al.
analyzed tilted and axial implants in 41 patients with atrophic maxillae; after a follow-up period of 12 months, they recorded a mean bone loss of 0.9 ± 0.4 mm in axial implants and of 0.8 ± 0.5 mm in tilted implants. In our study, a mean marginal bone loss of 0.7 ± 0.4 mm was observed, in accordance with the literature.

Patient satisfaction was very high, since the procedure proved less invasive and the treatment times were shorter than with other treatment options. In a study by Peñarrocha et al., patients with severe maxillary atrophy rehabilitated with angled and palatine implants showed very high satisfaction scores owing to the reduced time, cost and morbidity associated with the treatment provided. Erkarpers et al. likewise recorded very high satisfaction scores in patients with atrophic maxillae rehabilitated with conventional implants and immediate loading. The worst result in the present study was obtained for ease of cleaning (72 VAS). In this regard, it is important to ensure that the prosthesis design is easy to clean for patients that usually do not have adequate hygienic skills.

The major limitation of the present observational retrospective clinical study was the small sample of patients (N = 10). It is necessary to carry out studies with larger samples to confirm these results.

**Conclusion**

In our limited sample of patients with severe maxillary atrophy (Cawood and Howell Class V), the placement of dental implants in anatomical buttresses and remnant bone, rehabilitated with fixed full-arch prostheses, was found to be an adequate treatment option in the long term regarding implant survival, marginal bone loss and periimplant clinical parameters. Patient satisfaction was very high; however, it is important to design hygienic (flat or convex) prostheses to facilitate cleaning by the patient at home.
